Controlling DNA Methylation

Though life on earth is composed of a diverse range of organisms, some with many different types of tissues and cells, all these are encoded by a molecule we call DNA. The information required to build a protein is stored in DNA within the cells. Not all the message in the DNA is used in each cell and not all the message is used all the time. During cell differentiation, the cells become dedicated for their specific function which involves selectively activating some genes and repressing others. Gene regulation is an important event in the developmental biology and the biology of various diseases, but a more complex process.

In the bacteria there are distinct enzymes while one is capable of cleaving DNA, the other protects DNA by modification. The complementary function provided by the set of enzymes offers a defense mechanism against the phage infection and DNA invasion. The incoming DNA is cleaved sequence specifically by the class of enzymes called restriction endonuclease (REase). The host DNA is protected by the sequence specific action of matching set of enzymes called the DNA methyltransferase (MTase). The control of the relative activities of the REase and MTase is critical because a reduced ratio of MTase/REase activity would lead to cell death via autorestriction. However too high a ratio would fail to provide protection against invading viral DNA. In addition a separate group of proteins capable of controlling R-M proteins have been identified in various restriction-modification (R-M) systems which are called C proteins (Roberts *et al*., 2003).

A homolog of R-M C protein, named as C.BclI regulates the expression level of M.BclI (methyltransferase) in *E. coli* differently. In the absence of C.BclI, M.BclI was over-expressed and displayed relaxed specificity for methylation of non-cognate (non-specific or less specific) sites. However, in the presence of C.BclI and C box (the C.BclI binding sequence), the expression level of M.BclI was down regulated and M.BclI did not show relaxed specificity.

Balendiran's group at City of Hope collected the x-ray diffraction data on BL1-5 at SSRL. The crystal structure of C.BclI was determined to 1.8 Å resolution by anomalous dispersion methods, using mercury derivatives. The high-resolution crystal structure of C.BclI uncovers the presence of a helix-turn-helix (HTH) motif (Figure 1) and the potential to bend B-DNA around the C.BclI dimer (Figure 2). Furthermore interactions with DNA are likely mediated by residues on the surface of the HTH motif helices between 34 and 48 in the structure. Moreover by analogy (Hochschild *et al*., 1983; Bushman and Ptashne, 1988; Bushman *et al*., 1989) highly conserved residue Glu27 in the C family of proteins and partly conserved Asp31 residue in C.BclI may play a crucial role in the interaction with RNA polymerase and be important for transcriptional control.

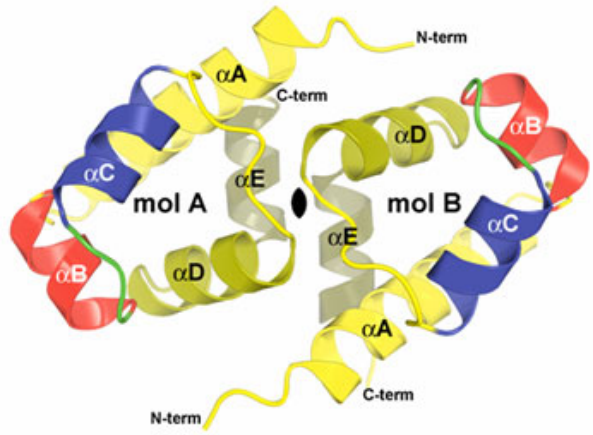

Figure 1. Dimer of C.BclI structure. Two molecules that form the dimer are related by a 2-fold rotational symmetry. There are five alpha helices (A, B, C, D, E) in each monomer of C.BclI and of them HTH motif is formed by the helices B and C.

Figure 2. Comparison of C.BclI structure with the known structures containing HTH motif. Induced DNA bending.
